Chapter 6. Advanced neuromonitoring

I. RECOMMENDATIONS

Strength of Recommendation: Weak.
Quality: Low, from one moderate- and one poor-quality class III study.

A. Level I

There are insufficient data to support a level I recommendation for this topic.

B. Level II

There are insufficient data to support a level II recommendation for this topic.

C. Level III

If brain oxygenation monitoring is used, maintenance of partial pressure of brain tissue oxygen (PbtO2) >10 mm Hg may be considered.

II. EVIDENCE TABLE (see Table 1)

III. OVERVIEW

Children with severe traumatic brain injury (TBI) frequently have abnormal cerebral hemodynamics, including intracranial hypertension, cerebral hypoxia, delayed and/or altered processing of electrophysiological signals, and impaired cerebral autoregulation. In addition to intracranial pressure (ICP) monitoring, advanced neuromonitoring techniques such as microdialysis, electrophysiological assessments, and examination of cerebral autoregulation may help identify and treat patients with these derangements after TBI. The development of advanced monitoring systems to provide information regarding both cerebrovascular and metabolic function after TBI is critical to providing optimal neurocritical care. If treatment preventing unwanted cerebral pathophysiological processes is shown to improve outcome in children with severe TBI, the use of monitoring systems, beyond ICP monitoring, will mark an important advance in the care of patients with TBI. Advanced neuromonitoring techniques may provide useful information about derangements in cerebral oxygenation, blood flow and metabolism, autoregulation, and function after severe pediatric TBI.

IV. PROCESS

For this new topic, MEDLINE was searched from 1950 through 2010 (Appendix B for search strategy), and results were supplemented with literature recommended by peers or identified from reference lists. Of 44 potentially relevant studies, two were included as evidence for this topic.

V. SCIENTIFIC FOUNDATION

Two class III publications met the inclusion criteria for this topic and provide evidence to support the recommendations (1, 2). The recommendations on the use of advanced neuromonitoring in this chapter are for patients with no contraindications for neuromonitoring such as coagulopathy (brain oxygenation) and for patients who do not have a diagnosis of brain death.

In 2009, a study by Figaji et al (1) reported the relationship between PbtO2 and long-term outcome in 52 children with severe TBI. Patients with compromised PbtO2 were treated to a threshold >20 mm Hg. Overall mortality was nearly 10%. After considering other conventional predictors, authors reported that PbtO2 <5 mm Hg for >1 hr or <10 mm Hg for >2 hrs were associated with a significantly increased risk of unfavorable outcome (Glasgow Outcome Scale and Pediatric Cerebral Performance Category scores) and mortality, independent of other factors that were also significant (e.g., ICP, cerebral perfusion pressure, Glasgow Coma Scale, computed tomography classification, and systemic hypoxia). This study provided no comparison group. All patients with compromised PbtO2 were treated to maintain the targeted threshold, and at the same time they may have received various treatments depending on other physiological variables such as ICP, cerebral perfusion pressure, systemic oxygen, and hemoglobin. What can be inferred is that in this sample of patients, those with higher PbtO2 and fewer episodes of PbtO2 <10 mm Hg had better outcomes. We cannot say that this relationship is a direct response to treatment.

In 2006, a study by Narotam et al (2) described changes in PbtO2 in relation to changes in cerebral perfusion pressure, FIO2, and Pao2 in 15 children ranging from 1.5 to 18 yrs and Glasgow Coma Scale score ≥8. Like with the previous study, patients were managed to maintain a PbtO2 level ≥20 mm Hg. In addition, the authors aimed to assess a treatment protocol (Critical Care Guide) for manipulation of physiological factors that influence oxygen delivery to the brain. Survival was associated with normal initial PbtO2 (≥10 mm Hg). There was no difference in the mean initial PbtO2 among the ten survivors and six deaths at 3 months. Final PbtO2 in survivors was higher than that in nonsurvivors (mean PbtO2 22.7 ± 9.05 vs. 7.2 ± 7.85 mm Hg; p = .0045). However, only six patients had elevated ICP, making the relationship between ICP and PbtO2 difficult to interpret. Like with the previous study, we cannot infer from this study that response to treatment influenced outcome.

In these two studies, a treatment threshold for PbtO2 of 20 mm Hg was used; however, they both reported an association between unfavorable outcome and PbtO2 <10 mm Hg. Although the study by Figaji et al (1) reported an even stronger association between PbtO2 <5 mm Hg and unfavorable outcome, until proven otherwise, if this advanced monitoring modality is used, it would be prudent to target the more conservative threshold of >10 mm Hg.

VI. INFORMATION FROM OTHER SOURCES

Several articles on advanced neuromonitoring in the pediatric TBI literature were identified in the search but excluded from the evidentiary table because they simply described use of a given advanced neuromonitoring device rather than targeting a treatment value for that monitor (i.e., a threshold parameter on
and PbtO2 monitoring, in addition to

tion for use of jugular venous saturation

Similarly, low values of PbtO2 (when using this monitoring technique.

treatment threshold

value represents a treatment threshold

associated with poor outcome and that this

suggests that episodes of jugular venous

desaturation (saturation

ment of adults with severe TBI. Evidence

suggests that episodes of jugular venous

desaturation (saturation <50%) are asso-
ciated with poor outcome and that this

value represents a treatment threshold

using this monitoring technique. Similarly, low values of PbtO2 (<15 mm

Hg) and the extent of their duration (>30

mins) are associated with high rates of mortality and that 15 mm Hg represents a treatment threshold value for PbtO2. However, the accuracy of jugular venous saturation and PbtO2 monitoring was not evaluated. Although many technologies including cerebral microdialysis, thermal diffusion probes, transcranial Doppler, and near-infrared spectroscopy were recognized to hold promise in advancing the care of adults with severe TBI, there was insufficient evidence to comment on the use of these advanced neuromonitors in this population.

VIII. KEY ISSUES FOR FUTURE INVESTIGATION

- Examine critical thresholds for each neuromonitoring modality and de-
termine the risk-benefit ratio, cost-effectiveness, comparative effectiveness, and impact of neuromonitors on patient long-term functional outcomes.
- Address issues of single vs. multi-
omodal neuromonitoring, reliability of technology, optimal combination of monitors, location of neuromonitor vs. site of injury (hemispheric, pericontusional), relationship between neuromonitor data and imaging data, neuromonitor use for optimization of treatment and patient

the advanced monitoring device was not

specifically manipulated). Given that this
guidelines document is focused on treat-
ment, for these reports, a treatment rec-
ommendation regarding the monitoring
device could not be given. The devices in
those studies included brain microdialysis
(3), cerebral blood flow and autoregulation monitors (4–7), signal processing of hemo-
dynamic and hydrostatic signals (8), and jugular venous oxygen saturation monitor-
ing (9).

A. Indications From the Adult

Guidelines

Evidence from the adult guidelines (10) supported a level III recommendation for use of jugular venous saturation and PbtO2 monitoring, in addition to standard ICP monitors, in the manage-
ment of adults with severe TBI. Evidence

suggests that episodes of jugular venous

desaturation (saturation <50%) are asso-
ciated with poor outcome and that this

value represents a treatment threshold

when using this monitoring technique.
